(Dated: August 21, 2015)

**Background:** Identification of proton-neutron mixed-symmetric one quadrupole-phonon excitations (the  $2_{ms}^+$  states) of atomic nuclei provides information on the isovector part of the residual nucleon-nucleon interaction. It was predicted that the  $2_{ms}^+$  state of particular nuclei close to the  $U(5)$  limit of the Interacting Boson Model, in particular  $^{140}\text{Ba}$ , should be considerably populated by  $\alpha$ -transfer reactions [1].

**Purpose:** We aim at the identification of the  $2_{ms}^+$  state (MSS) of radioactive  $^{140}\text{Ba}$  and investigate its population by the  $\alpha$ -transfer reaction as a potential new tool to selectively populate MSSs as a potential new signature for its mixed-symmetric character.

**Method:** A  $\gamma$ -ray spectroscopy experiment was performed in inverse kinematics in order to populate the  $2_{ms}^+$  state of  $^{140}\text{Ba}$  by  $\alpha$ -transfer from a  $^{nat}\text{C}$  target on  $^{136}\text{Xe}$  beam ions. The population of the candidate for the  $2_{ms}^+$  state of  $^{140}\text{Ba}$  was measured relative to the population of the  $2_1^+$  state.

**Results:** The candidate for the  $2_{ms}^+$  state of  $^{140}\text{Ba}$  was populated by  $\alpha$ -transfer, however, three times weaker than predicted. Another  $2^+$  state that can be ruled out as the MSS was in turn as strongly populated by the  $\alpha$ -transfer as predicted for the MSS.

**Conclusions:** The relative population of  $2^+$  states by  $\alpha$ -transfer cannot serve as a new signature for MSSs, since (also) other  $2^+$  states are strongly populated. Nevertheless, the substantial population of the MSS candidate of  $^{140}\text{Ba}$  by  $\alpha$ -transfer qualifies this type of reaction as suitable tool to excite MSSs and study their electromagnetic decay properties.

Keywords: Mixed-Symmetry States, Alpha-Transfer

## I. INTRODUCTION

Proton-neutron mixed-symmetry one-quadrupole phonon excitations, the  $2_{ms}^+$  states, are isovector valence-space excitations of even-even atomic nuclei [2, 3]. They exist in (near-) spherical vibrators with a few pairs of protons and neutrons outside of doubly-closed shells and exhibit a non-maximum  $F$ -spin [4, 5] with  $F = F_{max} - 1$  in the framework of the proton-neutron version of the Interacting Boson Model (IBM-2) [4]. In the same framework and the simple situation of one proton and neutron boson, each, the one-phonon

mixed-symmetry  $2^+$  states  $|2_{ms}^+\rangle$  can be expressed as out-of-phase excitation of protons ( $\pi$ ) and neutrons ( $\nu$ ):

$$|2_{ms}^+\rangle = \frac{1}{\sqrt{2}}(d_{\pi}^{\dagger}s_{\nu}^{\dagger} - s_{\pi}^{\dagger}d_{\nu}^{\dagger})|0\rangle. \quad (1)$$

Here,  $s_{\pi(\nu)}^{\dagger}$  and  $d_{\pi(\nu)}^{\dagger}$  denote the proton (neutron)  $s$ - and  $d$ -boson creation operators, respectively.  $|0\rangle$  denotes the boson-vacuum state. In contrast to the mixed-symmetric state defined in Eq. (1), the fully-symmetric one quadrupole-phonon state  $2_{FS}^+$ , i.e. the  $2_1^+$  state of an even-even nucleus, is given by the respective in-phase excitation of protons and neutrons:

$$|2_{FS}^+\rangle = \frac{1}{\sqrt{2}}(d_{\pi}^{\dagger}s_{\nu}^{\dagger} + s_{\pi}^{\dagger}d_{\nu}^{\dagger})|0\rangle. \quad (2)$$

Equations (1) and (2) are valid in the  $U(5)$  limit of the IBM-2, i.e. for spherical vibrators. The interest in mixed-symmetry states (MSSs) arises from their sensitivity to the proton-neutron part of the residual interaction  $V_{pn}$  [6].

The prime experimental signature for  $2_{ms}^+$  states is their strong  $M1$  decay to the fully-symmetric  $2_1^+$  state with an absolute matrix element in the order of

$\langle 2_{ms}^+ | M1 | 2_{FS}^+ \rangle \approx 1 \mu_N$  and a weakly collective decay strength to the ground state of  $B(E2, 2_{ms}^+ \rightarrow 0_1^+) \approx 1 \text{ W.u.}$  The strong  $M1$  transition leads to short lifetimes of  $2_{ms}^+$  states in the order of 100 fs. In particular situations, alternative experimental signatures for  $2_{ms}^+$  states exist that are independent from their electromagnetic decay properties, for example the difference in transition radii of the  $2_{FS}^+$  and  $2_{ms}^+$  states [7]. Furthermore, Alonso *et al.* have investigated the population of  $2_{ms}^+$  states by  $\alpha$ -transfer reactions in the framework of the IBM-2 [1]. They found that in the  $U(5)$ -limit of spherical vibrators, the population of the  $2_{ms}^+$  state in  $\alpha$ -transfer reactions should be as strong as 1/3 relative to the population of the  $2_1^+$  state.

The first candidates for  $2_{ms}^+$  states were claimed in the  $N = 84$  isotones  $^{140}\text{Ba}$ ,  $^{142}\text{Ce}$  and  $^{144}\text{Sm}$  based on the small  $E2/M1$  multipole mixing ratio of their decays to the  $2_1^+$  state [8]. In the stable nuclei  $^{142}\text{Ce}$  and  $^{144}\text{Sm}$ , the  $2_{ms}^+$  states were uniquely established [9, 10] by measurements of their absolute  $B(M1)$  transition strengths to the  $2_1^+$  states. In radioactive  $^{140}\text{Ba}$ , however, the confirmation of the candidate  $2^+$  state at 1993.7 keV as the  $2_{ms}^+$  state is still pending.

In the work of Alonso *et al.*, the nucleus  $^{140}\text{Ba}$  was identified as the ideal candidate for comparatively strong population of the  $2_{ms}^+$  state by  $\alpha$ -transfer from  $^{12}\text{C}$  nuclei [1]. Therefore, we conducted a  $\gamma$ -ray spectroscopy experiment in inverse kinematics aiming at the population of the  $2_{ms}^+$  state in radioactive  $^{140}\text{Ba}$  by the transfer of  $\alpha$ -particles from  $^{12}\text{C}$  target nuclei to a beam of  $^{136}\text{Xe}$ .

## II. EXPERIMENTAL DETAILS

In  $\alpha$ -transfer reactions, a  $^4\text{He}$  nucleus is exchanged between a projectile and a target nucleus. Albeit the details of  $\alpha$ -transfer reactions are not fully understood [1], it is well-known that preferably low-spin states are excited in  $\alpha$ -transfer reactions [11] and that its cross section is largest for swift collisions, i.e. for collisions where the distance of closest approach between projectile and target nuclei approximately equals the sum of their radii [12]. Therefore, maximum cross section can be expected for beam energies just at the Coulomb barrier. At these beam energies, the  $\alpha$ -transfer will compete with Coulomb excitation and other transfer reactions as well as fusion-evaporation. A clean identification of the  $\alpha$ -transfer reaction channel is therefore mandatory.  $\alpha$ -transfer has been successfully used for the population of excited states in radioactive nuclei close to the valley of stability in several experiments, e.g. [13, 14].

We have performed an experiment employing the inverse-kinematics reaction  $^{12}\text{C}(^{136}\text{Xe}, ^{140}\text{Ba})^8\text{Be}$  at the Laboratori Nazionali di Legnaro (LNL) in order to populate excited states of radioactive  $^{140}\text{Ba}$ . A beam of  $^{136}\text{Xe}$  was provided by LNL's PIAVE/ALPI accelerator complex with an intensity of 0.5 – 1 pA throughout the measurement. Runs were performed at two dif-

ferent beam energies of 500 and 546 MeV, respectively. The beams impinged on a self-supporting target made of  $^{nat}\text{C}$  with a thickness of 0.915(11) mg/cm<sup>2</sup>. Target-like reaction products were detected by an annular double-sided silicon-strip detector (DSSSD) with an inner (outer) active diameter of 32(85) mm and a thickness of  $\sim 300 \mu\text{m}$ . The DSSSD was placed at a distance of 33.4 mm downstream of the target and covered polar angles from  $\theta_{p,<} = 25.6^\circ$  to  $\theta_{p,>} = 51.8^\circ$  in the laboratory frame. The DSSSD was segmented into 32 rings in polar angle and 64 segments in azimuth angle, where always two adjacent azimuth segments were electrically combined resulting in 32 effective azimuth segments.  $\gamma$ -rays were observed with the AGATA demonstrator [15], consisting of 15 high-purity germanium crystals at the time of the measurement. The AGATA demonstrator was placed in backward direction and covered polar angles from  $\theta_{\gamma,<} \approx 74^\circ$  to  $\theta_{\gamma,>} \approx 164^\circ$ . X-rays and low-energy  $\gamma$ -rays were shielded by 1 mm copper- and 2 mm lead-plates in order to reduce the load of the data acquisition system. Data was recorded in particle- $\gamma$  coincidence mode. The reaction kinematics is shown in Figure 1.

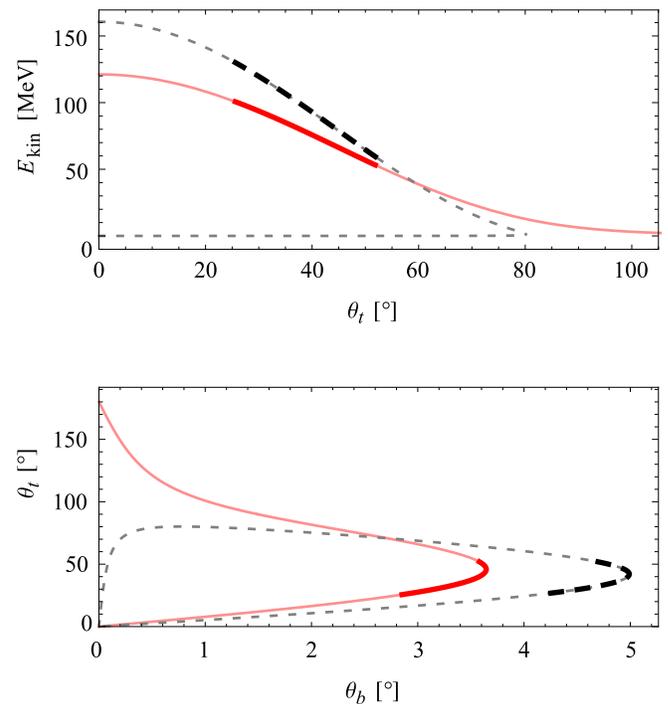

FIG. 1. (Color online) Reaction kinematics at 546 MeV beam energy for the  $\alpha$ -transfer reaction (red, solid line) and for Coulomb excitation (black, dashed line) for comparison. The polar-angular range covered by the DSSSD is indicated by the bold lines.

Top: Kinetic energy  $E_{kin}$  of the beam-like reaction product ( $^{140}\text{Ba}$ ,  $^{136}\text{Xe}$ ) plotted against the laboratory scattering angle  $\theta_t$  of the target-like reaction product ( $^8\text{Be}$ ,  $^{12}\text{C}$ ).

Bottom: Laboratory scattering angle  $\theta_p$  of the beam-like reaction product plotted against the laboratory scattering angle  $\theta_t$  of the target-like reaction product.

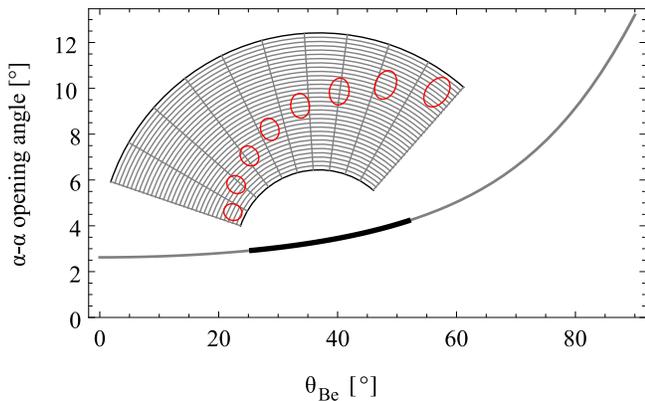

FIG. 2. (Color online) Maximum opening-angle of two  $\alpha$ -particles produced by the breakup of an  $^8\text{Be}$  nucleus, the target-like residual of an  $\alpha$ -transfer reaction (gray line). The opening angle is plotted against the laboratory scattering angle of the  $^8\text{Be}$  nucleus. The polar-angular range covered by the DSSSD is marked by the black, bold line. The two  $\alpha$ -particles are always detected in the same or in adjacent azimuth segments of the DSSSD, but may be detected in non-adjacent rings (the maximum separation of the two  $\alpha$ -particles for eight central emission angles of  $^8\text{Be}$  particles is depicted by the red ovals in the inset). The figure refers to 546 MeV beam energy.

### A. Reaction channel selection

The residual of the  $^{12}\text{C}$  target nuclei after an  $\alpha$ -transfer reaction,  $^8\text{Be}$ , is unstable and immediately breaks up into two  $\alpha$ -particles with a Q-value of 91.8 keV. Since the kinetic energy of the target-like product  $^8\text{Be}$  is a function of its scattering angle in the laboratory system (see Figure 1 bottom), also the maximum opening angle of the two  $\alpha$ -particles from the  $^8\text{Be}$  breakup is a function of the original  $^8\text{Be}$  scattering angle. This maximum opening angle is shown in Figure 2. The coincident detection of two  $\alpha$ -particles at close distance is a clean signal for an  $\alpha$ -transfer reaction, since multiple  $\alpha$ -particles from other reactions such as fusion-evaporation do not exhibit this strong directional correlation.

The maximum separation of the two  $\alpha$ -particles once they impinge on the DSSSD is depicted in the inset of Figure 2 for eight different scattering angles of the target-like reaction product  $^8\text{Be}$ . Two  $\alpha$ -particles from an  $\alpha$ -transfer reaction will always be detected in the same or in two adjacent azimuth segments of the DSSSD. In contrast, they may hit rings that are not directly adjacent. An add-back algorithm that combines energies coincidentally measured in adjacent rings / segments of the DSSSD was applied. Therefore, the full sum-energy of two  $\alpha$ -particles from an  $\alpha$ -transfer reaction is always measured in the azimuth segments, but the energy of one of the  $\alpha$ -particles may be missed in the rings. The particle energies measured in one ring of the DSSSD at a beam energy of 546 MeV are plotted in Figure 3 against the energies measured in any of the azimuth segments. The off-diagonal events in Figure 3 represent the discussed case

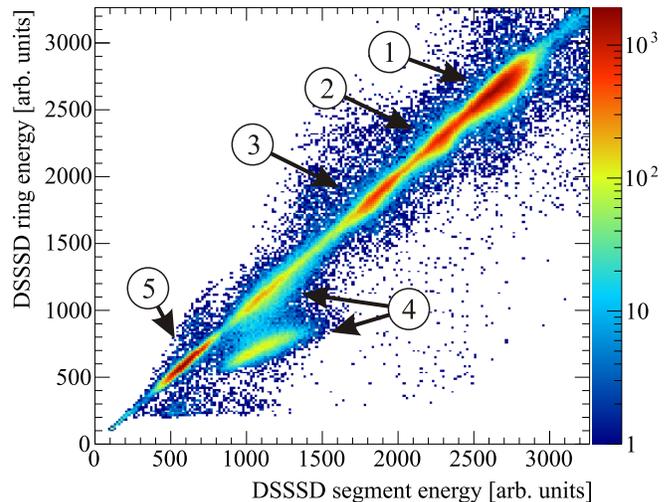

FIG. 3. (Color online) Spectrum of target-like particle energy measured in one ring of the DSSSD (covering  $\theta_p = \{32.1^\circ, \dots, 33.1^\circ\}$ , y-axis) plotted against the energy measured in any of the azimuth segments (x-axis). Different reaction channels can clearly be separated. The events marked with ① correspond to Coulomb-excitation, while the events marked with ④ correspond to  $\alpha$ -transfer. The other reactions are discussed in the text. Data taken at 546 MeV beam energy is shown.

where the energy of one of the two  $\alpha$ -particles from an  $\alpha$ -transfer reaction is missed by the add-back algorithm, because the particles hit two non-adjacent rings of the DSSSD.

The energies of the target-like reaction products at a given observation angle (or a given ring of the DSSSD) vary for the different occurring reactions, as exemplified in the top of Figure 1. This allows to separate the different reaction channels on an event-by-event basis as is clearly visible in Figure 3. The separation is best at small laboratory scattering angles of the target-like reaction products (see Figure 1 top).

By inspection of the corresponding  $\gamma$ -ray spectra, the events in Figure 3 marked with ① can be identified with the Coulomb-excitation of the  $^{136}\text{Xe}$  beam ions, the events marked with ④ correspond to  $\alpha$ -transfer reactions and the events marked with ②, ③ and ⑤ are dominated by the reactions  $^{12}\text{C}(^{136}\text{Xe}, ^{137}\text{Cs}^*)^{11}\text{B}$  (proton pick-up),  $^{12}\text{C}(^{136}\text{Xe}, ^{138}\text{Ba}^*)^{10}\text{Be}$  (two proton pick-up) and  $^{12}\text{C}(^{136}\text{Xe}, ^{140}\text{Ba}^*)2\alpha / ^{12}\text{C}(^{136}\text{Xe}, ^{142}\text{Ce}^*)\alpha+2n$  (fusion-evaporation reactions with  $\alpha$ -particles in the exit channel), respectively, as we could verify from the coincident  $\gamma$ -ray spectra. The analysis of the reactions channels other than  $\alpha$ -transfer will be discussed in forthcoming publications.

## B. $\gamma$ -ray spectra

The  $\gamma$ -ray spectra corresponding to events where the occurrence of an  $\alpha$ -transfer reaction was identified (see previous subsection) are shown in Figure 4 for both beam energies of 500 and 546 MeV, respectively. The spectrum is contaminated by transitions in the nucleus  $^{139}\text{Ba}$  that was presumably produced in the incomplete fusion reaction  $^{12}\text{C}(^{136}\text{Xe}, ^{139}\text{Ba}^*)\alpha + \alpha n$ . In this reaction, the target carbon ions break up into an  $\alpha$ -particle and an  $^8\text{Be}$  nucleus. The latter fuses with the  $^{136}\text{Xe}$  beam ions. Excited states of  $^{139}\text{Ba}$  are then populated in the  $\alpha n$  exit channel of the fusion product. In contrast to the evaporated  $\alpha$ -particles, the residual  $\alpha$ -particles from the  $^{12}\text{C}$  break-up are ejected with relatively high momentum and detected by the DSSSD at relatively high energy (see e.g. [17] for another observation of incomplete fusion reactions at similar experimental conditions). These residual  $\alpha$ -particles exhibit similar kinetic energy as the two  $\alpha$ -particles from  $\alpha$ -transfer reactions together. Therefore, the incomplete fusion events cannot be distinguished from the  $\alpha$ -transfer events by the measured particle energy. In the particle spectra as shown in Figure 3, they underlay the  $\alpha$ -transfer events for the case that the energy of both  $\alpha$ -particles has been measured (on-diagonal events in Figure 3). It is clearly visible in Figure 4 that the incomplete fusion reaction is strongly suppressed with respect to the  $\alpha$ -transfer reaction at the lower beam energy.

The statistics for the runs at 500 MeV beam energy is significantly lower since the duration of the measurement was much shorter than at 546 MeV beam energy. However, the decay pattern of  $^{140}\text{Ba}$  after  $\alpha$ -transfer and, hence, the  $\alpha$ -transfer excitation pattern is identical within the statistical uncertainties at both beam energies. This is well visible in Figure 4 and was also confirmed quantitatively. Therefore, only the high-statistics data set taken at 546 MeV beam is discussed in the following.

## III. POPULATION OF THE $2_{ms}^+$ CANDIDATE RELATIVE TO THE $2_1^+$ STATE

In order to assess the population of the  $2_{MSS}^+$  candidate relative to the  $2_1^+$  state, it is not sufficient to regard the observed  $\gamma$ -ray intensities discussed in the previous section. This is because the intensity of the  $2_1^+ \rightarrow 0_{gs}^+$  transition contains not only the cases where the  $2_1^+$  state was populated directly by the  $\alpha$ -transfer, but also the cases where the  $2_1^+$  state was fed by higher-lying states such as the  $4_1^+$ ,  $3_1^-$ ,  $2_2^+$  states etc. Consequently, the observed  $2_1^+ \rightarrow 0_{gs}^+$  intensity has to be purged from feeding before comparison to the observed intensity of the  $2_{MSS}^+$  candidate decays.

The transitions feeding the  $2_1^+$  state were identified from  $\gamma$ - $\gamma$  coincidence data with a gate on the  $2_1^+ \rightarrow 0_{gs}^+$  transition at 602.3 keV. All of them are marked in Figure

4. The  $4_1^+ \rightarrow 2_1^+$  transition at 528.3 keV and the  $6_1^+ \rightarrow 4_1^+$  transition at 529.7 keV cannot be separated in the  $\gamma$ -ray spectrum within the resolution after Doppler correction of 4.0(1) keV FWHM at 530 keV. The full intensity of the doublet peak near 530 keV contains the intensity of both transitions. Since the  $6_1^+$  state decays exclusively to the  $4_1^+$  state, only the intensity of the  $4_1^+ \rightarrow 2_1^+$  transition is relevant for the feeding analysis. However, the relative intensities of the  $4_1^+ \rightarrow 2_1^+$  and the  $6_1^+ \rightarrow 4_1^+$  transition in the doublet can be obtained from  $\gamma$ - $\gamma$  coincidence data. Feeding of the MSS candidate by  $\gamma$ -decays of higher-lying states has not been observed. A schematic level scheme with the relevant states and transitions is shown in Figure 5. The sum of transitions **a** and **a'** in Figure 5, i.e. the total intensity  $I_{a+a'}$  of the  $4_1^+ \rightarrow 2_1^+$  transition, is relevant for the feeding analysis. The total intensity of the doublet  $I_{doublet} = I_{a+a'+b}$  contains the transitions **a**, **a'** and **b** in Figure 5. Hence, the intensity  $I_b$  of the  $6_1^+ \rightarrow 4_1^+$  transition (transition **b**) has to be determined. Since transition **a'** contains only those decays of the  $4_1^+$  state where it was fed by the  $6_1^+$  state,  $I_{a'} = I_b$ .

Let  $I_{x|y}$  be the intensity of transition  $x$  obtained from  $\gamma$ - $\gamma$  coincidence data with a gate on transition  $y$ . Then, the intensity in the doublet after putting a gate on the  $2_1^+ \rightarrow 0_{gs}^+$  is given by

$$\begin{aligned} I_{doublet|2_1^+ \rightarrow 0_{gs}^+} &= I_{a|2_1^+ \rightarrow 0_{gs}^+} + I_{a'|2_1^+ \rightarrow 0_{gs}^+} + I_{b|2_1^+ \rightarrow 0_{gs}^+} \\ &= I_{a|2_1^+ \rightarrow 0_{gs}^+} + 2I_{b|2_1^+ \rightarrow 0_{gs}^+}. \end{aligned} \quad (3)$$

When a gate is put on the doublet itself, the transitions **a'** (coincident with **b**) and **b** (coincident with **a'**) can be accessed at the location of the doublet. The transition **a** excludes the cases where the  $4_1^+$  state has been fed by the  $6_1^+$  state. Hence, transition **a** is not coincident with transition **a'** or **b** and does not appear when a gate is set on the doublet. Therefore,

$$\begin{aligned} I_{doublet|doublet} &= I_{a'|doublet} + I_{b|doublet} \\ &= 2I_{b|doublet}. \end{aligned} \quad (4)$$

The contribution of the  $4_1^+$  decay to the total doublet intensity can be obtained from Eq. (3) and (4) when taking into account the  $\gamma$ -ray detection efficiencies  $\epsilon_y$  for the transitions that were gated on:

$$\frac{I_{4_1^+ \rightarrow 2_1^+}}{I_{doublet}} = \frac{I_{a+a'}}{I_{doublet}} = 1 - \frac{\epsilon_{2_1^+ \rightarrow 0_{gs}^+}}{2\epsilon_{doublet}} \frac{I_{doublet|doublet}}{I_{doublet|2_1^+ \rightarrow 0_{gs}^+}}. \quad (5)$$

With the aid of Equation (5), the fraction of the total  $4_1^+ \rightarrow 2_1^+$  transition in the doublet at 530 keV can be determined to be  $I_{4_1^+ \rightarrow 2_1^+}/I_{doublet} = 70.6 \pm 2.1\%$ .

Using the intensities listed in Table I and the ratio  $I_{4_1^+ \rightarrow 2_1^+}/I_{doublet}$ , the degree to which the  $2_1^+$  state is fed by higher-lying states can be inferred under the assumptions that all direct feeders of the  $2_1^+$  state are accounted for. No other transitions feeding the  $2_1^+$  state than those listed

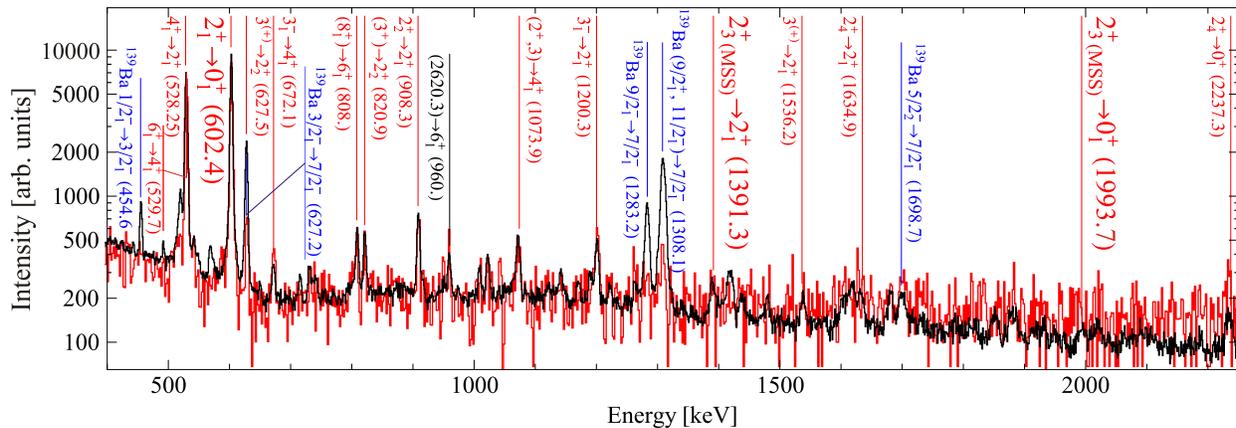

FIG. 4. (Color online) Doppler-corrected, random-subtracted  $\gamma$ -ray spectrum of  $^{140}\text{Ba}$  populated by  $\alpha$ -transfer. The spectra measured at 500 MeV and 546 MeV beam energy are shown in red and black, respectively. Selection of events corresponding to  $\alpha$ -transfer is discussed in section II A. The spectra are normalized such that they contain the same number of events in the  $2_1^+ \rightarrow 0_1^+$  transition at 602.4 keV. For the 500 MeV spectrum, the content of each two adjacent bins was added in order to reduce fluctuations. Transitions in  $^{140}\text{Ba}$  are marked by red lines and labels, contaminating transitions are marked by blue lines and labels. The transition energies are taken from [16]. See text for details.

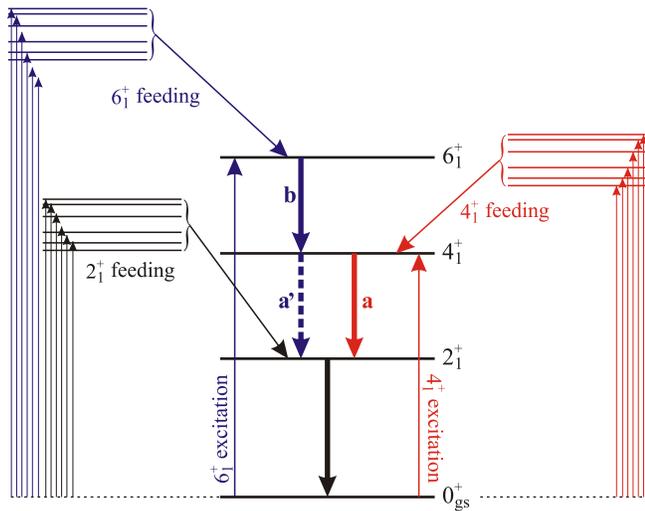

FIG. 5. (Color online) Schematic level scheme with the states and transitions relevant for the analysis of the  $2_1^+$  level feeding. The  $4_1^+ \rightarrow 2_1^+$  and the  $6_1^+ \rightarrow 4_1^+$  transition form a doublet in the  $\gamma$ -ray spectrum that cannot be resolved. This doublet contains the intensities from the direct population of the  $4_1^+$  state by the  $\alpha$ -transfer and its population from all higher-lying states except for the  $6_1^+$  state (red part of the figure, transition **a**), the decay of the  $4_1^+$  state fed by the  $6_1^+$  state (blue, dashed arrow, transition **a'**) as well as the decays of the  $6_1^+$  state, populated directly by the  $\alpha$ -transfer or from higher-lying states (remaining blue part, transition **b**). Further transitions feed the  $2_1^+$  state (left). See text for details.

in Table I were identified in the available  $\gamma$ - $\gamma$  coincidence data. Under these assumptions, the population of the candidate for the  $2_{ms}^+$  state relative to the population of the  $2_1^+$  state is 10.7(10)%. Both decay branches of the  $2_{ms}^+$  candidate, i.e. the transitions  $2_3^+(MSS) \rightarrow 2_1^+$

transition	upper level energy [keV]	intensity
$2_1^+ \rightarrow 0_{gs}^+$	602.4	39798(207)
$4_1^+ \rightarrow 2_1^+ / 6_1^+ \rightarrow 4_1^+$	1130.6 / 1660.3	31727(200)
$2_2^+ \rightarrow 2_1^+$	1510.7	3010(71)
$3_1^- \rightarrow 2_1^+$	1802.9	2046(64)
$2_3^+(MSS) \rightarrow 2_1^+$	1993.7	859(50)
$2_3^+(MSS) \rightarrow 0_{gs}^+$	1993.7	211(41)
$3^{(+)} \rightarrow 2_1^+$	2138.2	463(45)
$2_4^+ \rightarrow 2_1^+$	2237.2	738(49)

TABLE I. Relevant transition intensities from the analysis of  $\gamma$ -ray singles spectra at 546 MeV beam energy: Number of  $2_1^+ \rightarrow 0_{gs}^+$  transitions, number of the decays of the candidate for the  $2_{ms}^+$  state and intensities of transitions feeding the  $2_1^+$  state. The  $4_1^+ \rightarrow 2_1^+$  and the  $6_1^+ \rightarrow 4_1^+$  form a doublet that cannot be resolved. Their relative intensity is obtained from the analysis of  $\gamma$ - $\gamma$  coincidence data (see text for details). The level energies are taken from [16].

and  $2_3^+(MSS) \rightarrow 0_{gs}^+$ , have been considered. If any direct feeders of the  $2_1^+$  state have been missed here, the quoted relative population represents a lower limit.

#### IV. DISCUSSION & CONCLUSION

The only candidate for the  $2_{ms}^+$  state of  $^{140}\text{Ba}$  is the  $2_3^+$  state at 1993.7 keV excitation energy [8]. This assignment is based on its small  $E2/M1$  multipole mixing ratio  $\delta = 0.18_{-0.06}^{+0.05}$  determined in  $\beta$ -decay measurements [16]. Furthermore, the level energy is consistent with the systematics of  $2_{ms}^+$  states in nearby nuclei [18]. No other  $2_1^+$  state with spectroscopic properties indicating mixed-

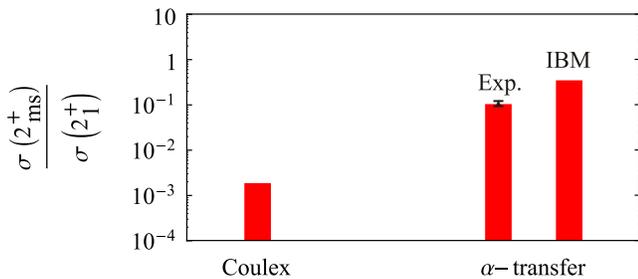

FIG. 6. (Color online) Cross section ratio for population of the  $2_1^+$  and  $2_{ms}^+$ -state of  $^{140}\text{Ba}$  by Coulomb-excitation (Coulomb) and  $\alpha$ -transfer. See text for details.

symmetric character is otherwise known in  $^{140}\text{Ba}$  [16].

The population of the MSS candidate by  $\alpha$ -transfer measured in this work is 10.7(10)% relative to the  $2_1^+$  state. This is a factor of three lower than the prediction by Alonso *et al.* of a relative population of the MSS in  $^{140}\text{Ba}$  of 1/3 of the  $2_1^+$ -state [1]. A strong fragmentation of the MSS can be ruled out, since no other  $2^+$  state with suitable decay characteristics has been found at nearby energies.

Besides the  $2_3^+$  state, the  $2_2^+$  state of  $^{140}\text{Ba}$  at 1510.7 keV excitation energy is strongly populated by the  $\alpha$ -transfer reaction with an intensity of 25.6(19)% relative to the  $2_1^+$  state (feeding of the  $2_2^+$  state from higher-lying states has been accounted for). This strong population is close to the prediction for the MSS by Alonso *et al.*, yet the  $2_2^+$  state can be ruled out as the  $2_{ms}^+$  state due to the strong  $E2$  component of its decay to the  $2_1^+$  state ( $\delta = -0.6_{-0.17}^{+0.18}$  [16]), the missing decay branch to the ground state and its excitation energy not fitting the systematics of MSSs in nearby nuclei.

In Figure 6, the observed and predicted population of the (only candidate for the) MSS of  $^{140}\text{Ba}$  by  $\alpha$ -transfer relative to the  $2_1^+$  state is compared to the same ratio for Coulomb-excitation of the  $2_{ms}^+$  and  $2_1^+$ -state of  $^{140}\text{Ba}$ . For the calculation of the Coulomb-excitation cross section, the value of the matrix-elements for the  $2_1^+$  state from [19] were used and for the  $2_{ms}^+$ -state, the value  $B(E2, 0_1^+ \rightarrow 2_{ms}^+) \approx 0.75 \text{ W.u.}$  was calculated according to the expression given in [20] for the  $U(5)$ -limit of the IBM-2. A "safe" bombarding energy of 411 MeV was

assumed according to Cline's criterion [21]. Clearly, the MSS is much stronger excited relative to the  $2_1^+$ -state by  $\alpha$ -transfer than by Coulomb-excitation. Due to this strong relative population of the  $2_{ms}^+$  state, the  $\alpha$ -transfer reaction can serve as a valuable tool to study the decay properties of MSSs in radioactive nuclei by experiments employing stable ions beams albeit the cross section for the excitation of the  $2_1^+$  state by  $\alpha$ -transfer is significantly lower than by Coulomb-excitation. In the case of  $\alpha$ -transfer experiments, MSS can also be identified without the information on transition strengths that is obtained in Coulomb-excitation experiments.  $M1$  transition strengths of MSS candidate decays to the fully symmetric  $2^+$ -state could be determined by the measurement of the  $2_{ms}^+$  level lifetime, e.g. by the Doppler-Shift Attenuation Method (DSAM), and the determination of the transition's multipole mixing ratio via the analysis of  $\gamma$ -ray angular distributions.

*In conclusio*, strong population of the MSS in  $^{140}\text{Ba}$  by  $\alpha$ -transfer was observed, yet not as strong as predicted by Alonso *et al.*. This assumes that the only candidate for the  $2_{ms}^+$  state indeed is the mixed-symmetry state. That another  $2^+$  state is the  $2_{ms}^+$  state or that the MSS is strongly fragmented can be ruled out by the available spectroscopic data. Besides the candidate for the  $2_{ms}^+$  state, the  $2_2^+$  state was nearly as strongly populated by  $\alpha$ -transfer as predicted for the MSS. However, the  $2_2^+$  state can be ruled out as the  $2_{ms}^+$  state. Hence, strong population of a  $2^+$  state by  $\alpha$ -transfer cannot serve as a unique signature for the mixed-symmetric character of the state. Nevertheless,  $\alpha$ -transfer can serve as a useful reaction mechanism for the study of the decay properties of MSSs of some radioactive isotopes in experiments with stable ion beams.

## ACKNOWLEDGMENTS

We thank the accelerator crew of the Laboratori Nazionali di Legnaro for providing the Xenon beam, and K.-H. Speidel, A. Vitturi, O. Möller, G. Rainovski and V. Werner for fruitful discussions. This work was supported by HIC for FAIR and the German BMBF under grants No. 05P09RDFN4 and 05P12RDFN8.
